nlmrt-vignette

John C. Nash

November 16, 2024

Background

This vignette discusses the R package `nlmrt`, that aims to provide computationally robust tools for nonlinear least squares problems. Note that R already has the `nls()` function to solve nonlinear least squares problems, and this function has a large repertoire of tools for such problems. However, it is specifically NOT indicated for problems where the residuals are small or zero. Furthermore, it frequently fails to find a solution if starting parameters are provided that are not close enough to a solution. The tools of `nlmrt` are very much intended to cope with both these issues.

The functions are also intended to provide stronger support for bounds constraints and to introduce the capability for **masks**, that is, parameters that are fixed for a given run of the function.

`nlmrt` tools generally do not return the large nls-style object. However, we do provide a tool `wrapnls` that will run either `nlxb` followed by a call to `nls`. The call to `nls` is adjusted to use the `port` algorithm if there are bounds constraints.

1 An example problem and its solution

Let us try an example initially presented by [5] and developed by [2]. This is a model for the regrowth of pasture. We set up the computation by putting the data for the problem in a data frame, and specifying the formula for the model. This can be as a formula object, but I have found that saving it as a character string seems to give fewer difficulties. Note the " " that implies "is modeled by". There must be such an element in the formula for this package (and for `nls()`). We also specify two sets of starting parameters, that is, the `ones` which is a trivial (but possibly unsuitable) start with all parameters set to 1, and `huetstart` which was suggested in [2]. Finally we load the routines in the package `nlmrt`.

```
> options(width=60)
> pastured <- data.frame(
+ time=c(9, 14, 21, 28, 42, 57, 63, 70, 79),
```

```
+ yield= c(8.93, 10.8, 18.59, 22.33, 39.35,
+          56.11, 61.73, 64.62, 67.08))
> regmod <- "yield ~ t1 - t2*exp(-exp(t3+t4*log(time)))"
> ones <- c(t1=1, t2=1, t3=1, t4=1) # all ones start
> huetstart <- c(t1=70, t2=60, t3=0, t4=1)
> require(nlmrt)
```

Let us now call the routine `nlsmnqb` (even though we are not specifying bounds). We try both starts.

```
> anmrt <- nlxb(regmod, start=ones, trace=FALSE, data=pastured)
> print(anmrt)
nlmrt class object: x
residual sumsquares =  4648.1  on  9 observations
    after  3    Jacobian and  4 function evaluations
  name            coeff          SE       tstat      pval      gradient    JSingval
t1               38.8378           NA         NA         NA   -2.95e-11           3
t2               1.00007           NA         NA         NA  -7.748e-10   1.437e-09
t3              0.998202           NA         NA         NA   1.889e-08   2.275e-16
t4              0.996049           NA         NA         NA    4.15e-08   5.091e-26
```

```
> anmrtx <- try(nlxb(regmod, start=huetstart, trace=FALSE, data=pastured))
> print(strwrap(anmrtx))

[17] "44"
[18] "32"
[19] "c(t1 = 69.9553722026373, t2 = 61.6818319271118, t3 ="
[20] "-9.20880204813341, t4 = 2.37778402563408)"
[21] "8.37588360361963"
[22] "c(-Inf, -Inf, -Inf, -Inf)"
```

```
  [23] "c(Inf, Inf, Inf, Inf)"
  [24] "integer(0)"
```

Note that the standard `nls()` of R fails to find a solution from either start.

```
  > anls <- try(nls(regmod, start=ones, trace=FALSE, data=pastured))
  > print(strwrap(anls))
[1] "Error in nlsModel(formula, mf, start, wts,"
[2] "scaleOffset = scOff, nDcentral = nDcntr) : singular"
[3] "gradient matrix at initial parameter estimates"
```

```
  > anlsx <- try(nls(regmod, start=huetstart, trace=FALSE, data=pastured))
  > print(strwrap(anlsx))
[1] "Error in nls(regmod, start = huetstart, trace ="
[2] "FALSE, data = pastured) : singular gradient"
```

In both cases, the `nls()` failed with a 'singular gradient'. This implies the Jacobian is effectively singular at some point. The Levenberg-Marquardt stabilization used in `nlxb` avoids this particular issue by augmenting the Jacobian until it is non-singular. The details of this common approach may be found elsewhere [4, Algorithm 23].

There are some other tools for R that aim to solve nonlinear least squares problems. We have not yet been able to successfully use the INRA package `nls2`. This is a quite complicated package and is not installable as a regular R package using `install.packages()`. Note that there is a very different package by the same name on CRAN by Gabor Grothendieck.

2 The `nls` solution

We can call `nls` after getting a potential nonlinear least squares solution using `nlxb`. Package `nlmrt` has function `wrapnls` to allow this to be carried out automatically. Thus,

```
  > awnls <- wrapnls(regmod, start=ones, data=pastured, control=list(rofftest=FALSE))
  > print(awnls)
Nonlinear regression model
  model: yield ~ t1 - t2 * exp(-exp(t3 + t4 * log(time)))
   data: data
   t1    t2    t3    t4
69.96 61.68 -9.21  2.38
 residual sum-of-squares: 8.38

Number of iterations to convergence: 0
Achieved convergence tolerance: 7.91e-08
```

```
  > cat("Note that the above is just the nls() summary result.\n")
Note that the above is just the nls() summary result.
```

3 Problems specified by residual functions

The model expressions in R , such as

`yield ~ t1 - t2*exp(-exp(t3+t4*log(time)))`

are an extremely helpful feature of the language. Moreover, they are used to compute symbolic or automatic derivatives, so we do not have to rely on numerical approximations for the Jacobian of the nonlinar least squares problem. However, there are many situations where the expression structure is not flexible enough to allow us to define our residuals, or where the construction of the residuals is simply too complicated. In such cases it is helpful to have tools that work with R functions.

Once we have an R function for the residuals, we can use the safeguarded Marquardt routine `nlfb` from package `nlmrt` or else the routine `nls.lm` from package `minpack.lm` [1]. The latter is built on the Minpack Fortran codes of [3] implemented by Kate Mullen. `nlfb` is written entirely in R , and is intended to be quite aggessive in ensuring it finds a good minimum. Thus these two approaches have somewhat different characteristics.

Let us consider a slightly different problem, called WEEDS. Here the objective is to model a set of 12 data points (density y of weeds at annual time points tt) versus the time index. (A minor note: use of `t` rather than `tt` in R may encourage confusion with the transpose function `t()`, so I tend to avoid plain `t`.) The model suggested was a 3-parameter logistic function,

$y_{model} = b_1/(1 + b_2 exp(-b_3 tt))$

and while it is possible to use this formulation, a scaled version gives slightly better results

$y_{model} = 100 b_1/(1 + 10 b_2 exp(-0.1 b_3 tt))$

The residuals for this latter model (in form "model" minus "data") are coded in R in the following code chunk in the function `shobbs.res`. We have also coded the Jacobian for this model as `shobbs.jac`

```
> shobbs.res <- function(x){ # scaled Hobbs weeds problem -- residual
+ # This variant uses looping
+     if(length(x) != 3) stop("hobbs.res -- parameter vector n!=3")
+     y <- c(5.308, 7.24, 9.638, 12.866, 17.069, 23.192, 31.443, 38.558, 50.156, 62.948,
+          75.995, 91.972)
+     tt <- 1:12
+     res <- 100.0*x[1]/(1+x[2]*10.*exp(-0.1*x[3]*tt)) - y
+ }
> shobbs.jac <- function(x) { # scaled Hobbs weeds problem -- Jacobian
+     jj <- matrix(0.0, 12, 3)
+     tt <- 1:12
+     yy <- exp(-0.1*x[3]*tt) # We don't need data for the Jacobian
+     zz <- 100.0/(1+10.*x[2]*yy)
+     jj[tt,1]  <-  zz
+     jj[tt,2]  <-  -0.1*x[1]*zz*zz*yy
+     jj[tt,3]  <-  0.01*x[1]*zz*zz*yy*x[2]*tt
```

```
+     return(jj)
+ }
```

With package `nlmrt`, function `nlfb` can be used to estimate the parameters of the WEEDS problem as follows, where we use the naive starting point where all parameters are 1.

```
> st <- c(b1=1, b2=1, b3=1)
> ans1 <- nlfb(st, shobbs.res, shobbs.jac, trace=FALSE)
> print(ans1)
nlmrt class object: x
residual sumsquares =  2.5873  on  12 observations
    after  10    Jacobian and  14 function evaluations
  name            coeff          SE       tstat      pval      gradient    JSingval
b1               1.96186        0.1131      17.35  3.166e-08  -7.327e-06       130.1
b2               4.90916        0.1688      29.08  3.282e-10   1.433e-07       6.165
b3                3.1357       0.06863      45.69  5.768e-12   1.717e-06       2.735
```

This works very well, with almost identical iterates as given by `nlxb`. (Since the algorithms are the same, this should be the case.) Note that we turn off the `trace` output. There is also the possibility of interrupting the iterations to `watch` the progress. Changing the value of `watch` in the call to `nlfb` below allows this. In this code chunk, we use an internal numerical approximation to the Jacobian.

```
> cat("No jacobian function -- use internal approximation\n")
No jacobian function -- use internal approximation
> ans1n <- nlfb(st, shobbs.res, trace=FALSE, control=list(watch=FALSE)) # NO jacfn
> print(ans1n)
nlmrt class object: x
residual sumsquares =  2.5873  on  12 observations
    after  10    Jacobian and  14 function evaluations
  name            coeff          SE       tstat      pval      gradient    JSingval
b1               1.96186        0.1131      17.35  3.166e-08  -7.327e-06       130.1
b2               4.90916        0.1688      29.08  3.282e-10   1.429e-07       6.165
b3                3.1357       0.06863      45.69  5.768e-12   1.719e-06       2.735
```

Note that we could also form the sum of squares function and the gradient and use a function minimization code. The next code block shows how this is done, creating the sum of squares function and its gradient, then using the `optimx` package to call a number of minimizers simultaneously.

```
> shobbs.f <- function(x){
+    res <- shobbs.res(x)
+    as.numeric(crossprod(res))
+ }
> shobbs.g <- function(x){
+    res <- shobbs.res(x) # This is NOT efficient -- we generally have res already calcula
+    JJ <- shobbs.jac(x)
+    2.0*as.vector(crossprod(JJ,res))
+ }
```

```
> require(optimx)
> aopx <- optimx(st, shobbs.f, shobbs.g, control=list(all.methods=TRUE))
> summary(aopx)

```

We see that most of the minimizers work with either the analytic or approximated gradient. The 'CG' option of function `optim()` does not do very well in either case. As the author of the original step and description and then Turbo Pascal code, I can say I was never very happy with this method and replaced it recently with `Rcgmin` from the package of the same name, in the process adding the possibility of bounds or masks constraints.

4 Converting an expression to a function

Clearly if we have an expression, it would be nice to be able to automatically convert this to a function, if possible also getting the derivatives. Indeed, it is possible to convert an expression to a function, and there are several ways to do this (references??). In package `nlmrt` we provide the tools `model2grfun.R`, `model2jacfun.R`, `model2resfun.R`, and `model2ssfun.R` to convert a model expression to a function to compute the gradient, Jacobian, residuals or sum of squares functions respectively. We do not provide any tool for converting a function for the residuals back to an expression, as functions can use structures that are not easily expressed as R expressions.

Below are code chunks to illustrate the generation of the residual, sum of squares, Jacobian and gradient code for the Ratkowsky problem used earlier in the vignette. The commented-out first line shows how we would use one of these function generators to output the function to a file named "testresfn.R". However, it is not necessary to generate the file.

First, let us generate the residuals. We must supply the names of the parameters, and do this via the starting vector of parameters `ones`. The actual values are not needed by `model2resfun`, just the names. Other names are drawn from the variables used in the model expression `regmod`.

```
  > # jres <- model2resfun(regmod, ones, funname="myxres", file="testresfn.R")
  > jres <- model2resfun(regmod, ones)
  > print(jres)
function (prm, yield = NULL, time = NULL)
{
    t1 <- prm[[1]]
    t2 <- prm[[2]]
    t3 <- prm[[3]]
    t4 <- prm[[4]]
    resids <- as.numeric(eval(t1 - t2 * exp(-exp(t3 + t4 * log(time))) -
        yield))
}
<environment: 0x55ec8891fef8>
  > valjres <- jres(ones, yield=pastured$yield, time=pastured$time)
  > cat("valjres:")
valjres:
  > print(valjres)

5 Using bounds and masks

The manual for `nls()` tells us that bounds are restricted to the 'port' algorithm.

```
lower, upper: vectors of lower and upper bounds, replicated to be as
          long as 'start'.  If unspecified, all parameters are assumed
          to be unconstrained.  Bounds can only be used with the
          '"port"' algorithm.  They are ignored, with a warning, if
          given for other algorithms.
```

Later in the manual, there is the discomforting warning:

```
The 'algorithm = "port"' code appears unfinished, and does not
even check that the starting value is within the bounds.  Use with
caution, especially where bounds are supplied.
```

We will base the rest of this discussion on the examples in man/nlmrt-package.Rd, and use an unscaled version of the WEEDS problem.

First, let us estimate the model with no constraints.

```
> require(nlmrt)
> # Data for Hobbs problem
> ydat <- c(5.308, 7.24, 9.638, 12.866, 17.069, 23.192, 31.443,
+           38.558, 50.156, 62.948, 75.995, 91.972)
> tdat <- 1:length(ydat)
> weeddata1 <- data.frame(y=ydat, tt=tdat)
> start1 <- c(b1=1, b2=1, b3=1) # name parameters for nlxb, nls, wrapnls.
> eunsc <-  y ~ b1/(1+b2*exp(-b3*tt))
> anlxb1 <- try(nlxb(eunsc, start=start1, data=weeddata1))
> print(anlxb1)
nlmrt class object: x
residual sumsquares =  2.5873  on  12 observations
    after  18    Jacobian and  25 function evaluations
  name            coeff          SE       tstat      pval      gradient    JSingval
b1               196.186         11.31      17.35  3.164e-08  -2.663e-07        1011
b2               49.0916         1.688      29.08  3.281e-10   1.59e-07       0.4605
b3               0.31357      0.006863      45.69  5.768e-12  -5.531e-05     0.04715
```

Now let us see if we can apply bounds. Note that we name the parameters in the vectors for the bounds. First we apply bounds that are NOT active at the unconstrained solution.

```
> # WITH BOUNDS
> startf1 <- c(b1=1, b2=1, b3=.1) # a feasible start when b3 <= 0.25
> anlxb1 <- try(nlxb(eunsc, start=startf1, lower=c(b1=0, b2=0, b3=0),
+       upper=c(b1=500, b2=100, b3=5), data=weeddata1))
> print(anlxb1)
nlmrt class object: x
residual sumsquares =  2.5873  on  12 observations
    after  13    Jacobian and  18 function evaluations
  name            coeff          SE       tstat      pval      gradient    JSingval
b1               196.186         11.31      17.35  3.164e-08  -2.662e-07        1011
b2               49.0916         1.688      29.08  3.281e-10   1.648e-07       0.4605
b3               0.31357      0.006863      45.69  5.768e-12  -5.872e-05     0.04715
```

We note that `nls()` also solves this case.

```
> anlsb1 <- try(nls(eunsc, start=startf1, lower=c(b1=0, b2=0, b3=0),
+      upper=c(b1=500, b2=100, b3=5), data=weeddata1, algorithm='port'))
> print(anlsb1)
Nonlinear regression model
  model: y ~ b1/(1 + b2 * exp(-b3 * tt))
   data: weeddata1
     b1      b2      b3
196.186  49.092   0.314
 residual sum-of-squares: 2.59

Algorithm "port", convergence message: relative convergence (4)
```

Now we will change the bounds so the start is infeasible.

```
> ## Uncon solution has bounds ACTIVE. Infeasible start
> anlxb2i <- try(nlxb(eunsc, start=start1, lower=c(b1=0, b2=0, b3=0),
+             upper=c(b1=500, b2=100, b3=.25), data=weeddata1))
> print(anlxb2i)
[1] "Error in nlxb(eunsc, start = start1, lower = c(b1 = 0, b2 = 0, b3 = 0),  : \n  Infeasible start\n"
attr(,"class")
[1] "try-error"
attr(,"condition")
<simpleError in nlxb(eunsc, start = start1, lower = c(b1 = 0, b2 = 0, b3 = 0),     upper = c(b1 = 500, b2 = 100, b3 = 0.25), data
> anlsb2i <- try(nls(eunsc, start=start1, lower=c(b1=0, b2=0, b3=0),
+             upper=c(b1=500, b2=100, b3=.25), data=weeddata1, algorithm='port'))
> print(anlsb2i)
[1] "Error in nls(eunsc, start = start1, lower = c(b1 = 0, b2 = 0, b3 = 0),  : \n  Convergence failure: initial par violates cons
attr(,"class")
[1] "try-error"
attr(,"condition")
<simpleError in nls(eunsc, start = start1, lower = c(b1 = 0, b2 = 0, b3 = 0),     upper = c(b1 = 500, b2 = 100, b3 = 0.25), data
```

Both `nlxb()` and `nls()` (with 'port') do the right thing and refuse to proceed. There is a minor "glitch" in the output processing of both `knitR` and `Sweave` here. Let us start them off properly and see what they accomplish.

```
> ## Uncon solution has bounds ACTIVE. Feasible start
> anlxb2f <- try(nlxb(eunsc, start=startf1, lower=c(b1=0, b2=0, b3=0),
+    upper=c(b1=500, b2=100, b3=.25), data=weeddata1))
> print(anlxb2f)
nlmrt class object: x
residual sumsquares =  29.993  on  12 observations
    after  13    Jacobian and  18 function evaluations
  name            coeff          SE       tstat      pval      gradient    JSingval

Algorithm "port", convergence message: both X-convergence and relative convergence (5)
```

Both methods get essentially the same answer for the bounded problem, and this solution has parameters `b1` and `b3` at their upper bounds. The Jacobian elements for these parameters are zero as returned by `nlxb()`.

Let us now turn to **masks**, which functions from `nlmrt` are designed to handle. Masks are also available with packages `Rcgmin` and `Rvmmin`. I would like to hear if other packages offer this capability.

```
> ## TEST MASKS
> anlsmnqm <- try(nlxb(eunsc, start=start1, lower=c(b1=0, b2=0, b3=0),
```

```
  +    upper=c(b1=500, b2=100, b3=5), masked=c("b2"), data=weeddata1))
  > print(anlsmnqm) # b2 masked
nlmrt class object: x
residual sumsquares =  6181.2  on  12 observations
    after  22    Jacobian and  35 function evaluations
  name           coeff          SE       tstat      pval      gradient    JSingval

6 Brief example of `minpack.lm`

Recently Kate Mullen provided some capability for the package `minpack.lm` to include bounds constraints. I am particularly happy that this effort is proceeding, as there are significant differences in how `minpack.lm` and `nlmrt` are built and implemented. They can be expected to have different performance characteristics on different problems. A lively dialogue between developers, and the opportunity to compare and check results can only improve the tools.

The examples below are a very quick attempt to show how to run the Ratkowsky-Huet problem with `nls.lm` from `minpack.lm`.

```
  > require(minpack.lm)
  > anlslm <- nls.lm(ones, lower=rep(-1000,4), upper=rep(1000,4), jres, jjac, yield=pastured
  > cat("anlslm from ones\n")
anlslm from ones
  > print(strwrap(anlslm))
 [1] "c(t1 = NaN, t2 = NaN, t3 = NaN, t4 = NaN)"
 [2] "c(NaN, NaN, NaN, NaN, NaN, NaN, NaN, NaN, NaN, NaN,"
 [3] "NaN, NaN, NaN, NaN, NaN, NaN)"
 [4] "c(NaN, NaN, NaN, NaN, NaN, NaN, NaN, NaN, NaN)"
 [5] "-1"
 [6] "Number of iterations has reached `maxiter' == 50."
 [7] "list(t1 = 3, t2 = NaN, t3 = NaN, t4 = NaN)"
 [8] "50"
 [9] "c(17533.3402000004, 16864.5616372991, NaN, NaN, NaN,"
[10] "NaN, NaN, NaN, NaN, NaN, NaN, NaN, NaN, NaN, NaN,"
[11] "NaN, NaN, NaN, NaN, NaN, NaN, NaN, NaN, NaN, NaN,"
